Abstract

**Background:** The clinical presentation of head injury may vary.

**Objective:** The purpose of the present study was to see the clinical features of patients presented with extra dural haematoma.

**Methodology:** This cross-sectional study was conducted in the Department of Neurosurgery at Dhaka Medical College Hospital, Dhaka, Bangladesh from January 2010 to June 2011 for a period of one year and six months. All patients who underwent surgery with traumatic head injury having extradural haematoma were included in the study. The clinical features of the patients were recorded.

**Result:** Eighty (80) patients of traumatic head injury within and after 24 hours of head injury were enrolled in this study. In this study unconsciousness was in 32(40.0%) cases. However, convulsion was found in 12 (15.0%). Vomiting was the most common presenting features which was 71(88.7%) cases. Headache was reported in 48(60.0%) cases. The normal pupillary response was found in 42(52.5%) cases. The rest 38(47.5%) cases were dilated pupil.

**Conclusion:** In conclusion vomiting is the most common clinical features of patients presented with extra dura haematoma. Vomiting followed by unconsciousness and headache.

**Keywords:** Extradural haematoma; traumatic head injury; clinical features

Introduction:
Head injury is a serious health problem in all nations¹. It is a significant factor for approximately half of all deaths related to trauma and the main cause of head trauma includes road traffic accident, assaults, fall from height, sports injuries and industrial accidents. Extradural haematomas (EDH) develops in 1.0 to 3.0% of all major head injuries²-⁴.

Extradural haematoma can result from injury to the middle meningeal artery, the middle meningeal vein, the diploic veins or the venous sinuses. Historically bleeding from the middle meningeal artery has been considered the main source for EDH. Extradural haematoma occurs in 2% of all serious head injuries; however, it is uncommon in infants and is associated with skull fracture.

Most typical clinical feature is the presence of lucid interval, during which headache, restlessness, nausea, vomiting, vertigo, confusion, poor reactivity or convulsion are observed. A head injury patient had only temporary loss of consciousness and was left asleep may sometimes be found dead in the bed next morning because of slowly developing extradural haematoma. The earliest neurosurgical abnormality other than disturbance of consciousness is pupillary abnormality, which amounts to 90.0% for mydriasis on the side of haematoma. It provides an important finding and helps in the localization of haematoma. This present study was undertaken to see the clinical features of patients presented with extra dural haematoma.

Methodology:
This cross-sectional study was carried out from January 2010 to June 2011 for a period of one year and six months. This study was carried out in the Department of Neurosurgery at Dhaka Medical College Hospital, Dhaka, Bangladesh. All patients who underwent surgery with traumatic head injury having extradural haematoma were included in the study. Purposive sampling technique was done. Patients with traumatic extradural haematoma diagnosed clinically by classical presentation of EDI-I and radiologically by non-contrast CT scan of brain all of whom underwent surgery. In all cases traumatic extradural haematoma were supratentorial. Non-traumatic extradural haematoma, patients with bilateral extradural haematoma, posterior fossa extradural haematoma and patients on anticoagulant therapy were excluded from this study. At admission, a detailed history of the illness was taken from the patients/patient’s attendants by face-to-face interview with the help of a pre-formed questionnaire. Questionnaire was prepared with key variables like age, sex and mode of injury. All the data were checked and edited after collection. Then the data were entered into computer and statistical analysis of the results was obtained by using window based computer software devised with Statistical Packages for Social Sciences (SPSS-16) (SPSS Inc, Chicago, IL, USA). Prior to the commencement of this study, the ethical committee of Dhaka Medical College, Dhaka, approved the thesis protocol. The aims and objectives of the study along with its procedure, risks and benefits of this study were explained to the respondents in easily understandable language and then written consent was taken from each. It was assured that all information and records would be kept confidential and the procedure would be helpful for the neurosurgeon and the patients in subsequent management.

Result:
Eighty (80) patients of traumatic head injury within and after 24 hours of head injury were enrolled in this study. 7(8.7%) patients were in the less than or equal to 10 years age group. 20(25.1%) patients were present in age group of 11 to 20 years. 19(23.8%) patients were in age group of 21-30 years. 20(25.1%) patients were present in age group of 31 to 40 years. 7(8.7%) patients were in the 41-50 years age group and more than 50 years in each. In this study the patient’s age ranged from 3 years to 64 years (Table 1).

Discussion:
Extradural hematoma (EDH) accounts for 2.0% of all head injuries\(^8\). In selected patients conservative management may be a feasible option. Although several reports have described successful conservative management of epidural hematoma, surgical evacuation constitutes definitive treatment of this condition\(^9\). Evacuation of the hematoma, coagulation of bleeding sites, and inspection of the dura follows the craniotomy. The dura is then tented to the bone and occasionally; epidural drains are employed for 24–48 hours\(^10\).

In this study eighty (80) patients of traumatic head injury within and after 24 hours of head injury were enrolled in this study. In this 7(8.7%) patients were in the less than or equal to 10 years age group. 20(25.1%) patients were present in age group of 11 to 20 years. 19(23.8%) patients were in age group of 21-30 years; however, 20(25.1%) patients were present in age group of 31 to 40 years. 7(8.7%) patients were in the 41-50 years age group and more than 50 years in each. In this study the patient’s age ranged from 3 years to 64 years. Extradural haematomas (EDH) usually occurs in young adults, and is rare before age 2 years or after age 60, perhaps because the dura is more adherent to the inner table in these groups\(^13\).

The extradural haematoma is a collection of blood between the skull and the dura mater. It is caused by a ruptured artery or vein in the epidural space as a result of a fracture of the skull at the moment of the impact in 60.0 to 90.0% of cases\(^14\). In children fractures are less common\(^15\).

In this study unconsciousness was in 32(40.0%) cases. However, convulsion was found in 12 (15.0%). Vomiting was the most common presenting features which was 71(88.7%) cases. Headache was reported in 48(60.0%) cases. Patients with EDH who are conscious have a very low mortality\(^7\). Only patients with loss of consciousness are at risk for the serious complication of herniation\(^11\). However, unconsciousness is the most common presentation of EDH patients. Furthermore there are several others clinical presentation are found in traumatic head injury. Among these presentation convulsion is a frequently reported in several studies\(^9-13\). This is due to the irritation in the meninges. In this study vomiting is reported in a significant number of patients. Therefore traumatic head injury followed by vomiting is not a good sign. In this situation proper management is essential for these patients.

Conclusion:
In conclusion vomiting is the most common clinical features of patients presented with extra dura haematoma is vomiting followed by unconsciousness and headache. Further large scale multicenter study should be carried out.
