

Effect of Nutrient Management on Population Growth of Brown Planthopper, *Nilaparvata lugens* (Stål)

M M Rashid¹, M Jahan², K S Islam², M N Bari³ and S S Haque⁴

ABSTRACT

Brown planthopper (BPH), *Nilaparvata lugens* (Stål) is a major insect pest of rice in Bangladesh. Nutrient management in rice received little attention on BPH population. The present study evaluated the consequences of nitrogen (N), phosphorus (P) and potassium (K) application on population build up and weight of BPH in the laboratory and net-house at Entomology Division, Bangladesh Rice Research Institute. Three levels of soil nitrogen (0, 100, 200 kg N ha⁻¹), phosphorus (0, 20, 40 kg P₂O₅ ha⁻¹) and potassium (0, 60, 120 kg K₂O ha⁻¹) were compared for individual and combined effects. Interactions of N, P and K demonstrated no significant effect on population growth and weight of BPH. However, interaction of N and P showed significant effect on population growth of BPH. Fertilization with nitrogen increased population and dry weight of BPH. Phosphorus fertilization markedly increased the population growth while high potassium application decreased population build up and dry weight of BPH.

Key words: BPH, nitrogen, phosphorus, potassium, growth, weight.

INTRODUCTION

Rice is the most important staple food worldwide and concerns the worlds' largest populations of farmers and consumers (Zeigler and Barclay, 2008). It is the predominant food crop of Bangladesh and occupies about 77% of the cropped areas and provides about 75% of the calorie and 55% of the protein in average daily diet of a Bangladeshi (Bhuiyan *et al.*, 2004). Recently brown planthopper (BPH), *Nilaparvata lugens* (Stål) (Homoptera: Delphacidae) has one of the most important insect pests of rice all over the world including Bangladesh (Ali *et al.*, 2014; Bottrell and Schoenly, 2012). Host plant quality plays a major role in the population biology of BPH. The plant nutrient status is an indicator of host plant quality, which plays an important role in the population dynamics of many herbivores (Cook and Denno, 1994). Nitrogen is one of the most important factors in development of phytophagous insects (Lu *et al.*, 2007). Populations of many insect species have been reported to increase significantly with higher nitrogen level (Dale, 1988; Chau *et al.*, 2003; Throop and Lerda, 2004; Hogendorp, 2006; Lu and Heong, 2009; El-Zahi *et al.*, 2012). There is a scope of greater population buildup of BPH (Preap *et al.*, 2001; Lu and Heong, 2009) resulting in a higher tendency for outbreaks in high nitrogen applied rice fields (Uhm *et al.*, 1985; Hosamani *et al.*, 1986; Li *et al.*, 1996).

Phosphorus (P) has not been considered as important or limiting as nitrogen for phytophagous insects including BPH. However, few studies that have been investigated the effects of phosphorus on different insects, which showed that it could be an important determinant of growth rate (Stern and Hessen, 1994; Elser *et al.*, 2000, 2001, 2003; Urabe and Stern, 2001; Eskelinen, 2002; Fagan *et al.*, 2002; Schade *et al.*, 2003; Perkins *et al.*, 2004)

and population density (Slamn, 2002; Schade *et al.*, 2003) of invertebrates. Phosphorus may be a much more important component for the population growth of phytophagous insects as it required for RNA synthesis. It can impose severe consequences for the growth rate of consumers i.e. invertebrates when it is limiting (Sterner and Elser, 2002).

Populations of many insect species have been reported to be affected adversely by K (Salim, 2002b; Sarwar *et al.*, 2011; El-Zahi, 2012; Sarwar, 2012). Potassium (K) is an essential element for the growth of rice plant and takes part in various physiological processes (Tisdale *et al.*, 1985; Wyn Jones, 1999). Amtmann (2008) reported that potassium nutrition has a profound effect on the profile and distribution of primary metabolites in plant tissues, which in turn could affect the attractiveness of the plant for insects as well as their subsequent growth and development on the plant. The primary metabolites such as soluble sugars particularly reducing sugars, organic acids and amino acids tend to increase in K deficient plants. It has been reported that the negative influence of high levels of K on insect populations is due to a reduced carbohydrate accumulation and elimination of amino acids (Baskaran *et al.*, 1985), higher silica content and increase in the sclerenchymous layer (Dale, 1988).

The studies on the effects of nitrogen, phosphorus and potassium on the population development of BPH are limited and have not been empirically tested in Bangladesh. Therefore, the present research work has been planned and designed to investigate the influence of plant nutrient levels on population build up and weight of BPH.

MATERIALS AND METHODS

Preparation of soil and host plant establishment

Soil was fertilized with 3 levels of nitrogen subsidy (0, 100, 200 kg N ha⁻¹), 3 levels of phosphorous (0, 20, 40 kg P₂O₅ ha⁻¹) and 3 levels of potassium (0, 60, 120 kg K₂O ha⁻¹) and combination of all the levels. The potted plants of different fertilizer doses were prepared separately for the experiments. Half of the N fertilizer (in the form of Urea) and the whole of P (in the form of Triple super phosphate, TSP) and K (in the form of Muriate of Potash, MP) were mixed in the soil. The remaining half of N was applied when the plants were 30-day-old. The macronutrient treatments are here after referred to as N₀, N₁₀₀ and N₂₀₀ for nitrogen, P₀, P₂₀ and P₄₀ for phosphorus and K₀, K₆₀ and K₁₂₀ for potassium. Fifteen-day-old rice seedlings of variety BR3 were transplanted (3 hills/pot and 2 seedlings/ hill) in each earthen pot. Plants with different fertilizer doses were labeled and placed under natural condition. As, one hectare cultivated field contains 2x10⁶ kg soil in its root zone. So, the exact amount of fertilizers inputs to be applied to each pot was calculated based on the amount of soil in each pot (Asher *et al.*, 2002).

Culture of brown planthopper

Brown planthopper (BPH) population required for the experiments were obtained from a mass culture maintained in the green house throughout the period of study with the susceptible variety BR3. Forty five to sixty-day-old potted rice plants were used for this purpose. The plants were cleaned and the outer leaf sheaths of the potted plants were removed to destroy the eggs of other insects if any. Those potted plants were kept in iron framed rearing cage covered by the fine mesh wire net on a tray filled with water to one-third of its height, so that the soil could not dry. Gravid BPH adults were released in a cage with the rice plants for oviposition and those removed 24 hours later using by an aspirator (a mouth sucking device). The potted plants with BPH eggs were then shifted every day to a

series of rearing cages for hatching of the eggs to ensure supply of same aged BPH. After hatching, the host plants in the cage were changed at 3-4 days interval to provide sufficient food for the development of the nymphs to adulthood. To obtain steady supply host plant materials for each BPH culture and experiment, seedlings were transplanted at 15-day intervals.

Nutrients experiments of brown planthopper

Yellow leaf sheaths were removed from forty-five day-old potted rice plants of different fertilizer doses and were infested with a pair of freshly molted adult for each treatment. The plants were covered with transparent mylar cages for population build up. Males and females were checked after 24 hours of infestation, and one pair of insects were ensured in each cage by eliminating the superfluous or by supplying additional. At 25 days after release of the adult all insects were collected in flasks containing ethyl acetone and counted. Fresh weight of twenty female adult BPH was measured to get mean fresh body weight and then all of the BPH were dried in the oven at 60 °C for 48 hours until constant weight and recorded total dry weight of BPH. Factorial (3x3x3) pot experiments were laid out in Completely Randomized Design (CRD) with 27 treatment combinations and four replications.

Statistical analysis

The data of number and dry weight of BPH was transformed into Square-Root transformation and those were analyzed using MSTAT-C programme. The mean differences among the treatments were compared by multiple comparison tests using Duncan's Multiple Range Test (DMRT) at 5% level.

RESULTS

Interactions of N and K, P and K, and all three nutrients (N, P and K) were insignificant for the brown planthopper population build up. The N and P interaction was significant on brown planthopper population development (Table 1). Number of BPH individuals in F₁ generation from one pair of adult BPH varied greatly by the application of nitrogen to the host plants. It was increased significantly with the increase of nitrogen application (Fig. 1). The highest number of brown planthopper (207.6) was recorded in the plants fertilized with the treatment N₂₀₀ (Table 2). There were also marked increases of population build up of brown planthopper when reared on the higher phosphorus regimes (Fig. 1). Number of brown planthopper produced from one pair of adult did not differ significantly in the treatments of P₂₀ and P₄₀ (Table 3). BPH population was reduced significantly at the highest rate of potassium (K₁₂₀) fertilized plants (Fig. 1). However, population build up was comparable between K₀ and K₆₀ fertilized plants (Table 4). Dry weight of BPH from one pair of adults varied greatly by the application of nitrogen to their host plants and increased significantly with the increase of nitrogen application (Fig. 2). The highest dry weight (62.92) was recorded in the plants by the application of 200 kg N ha⁻¹ (Table 2). There were also marked increases of dry weight of female brown planthopper when reared on the higher phosphorus regimes (Fig. 2). However, dry weight gained from one pair of adults did not differ significantly in the application of P₂₀ and P₄₀ (Table 3). The N and P interaction was significant on dry weight of BPH (Table 1). Dry weight of BPH was reduced significantly at the highest rate of potassium (K₁₂₀) fertilized plants (Fig. 2). However, there was no significant difference in K₀ and K₆₀ treatments (Table 4). Interaction of N and K, P and K, and

all three nutrients (N, P and K) were insignificant for the dry weight gained of brown planthopper (Table 1).

The nitrogen fertilization to the rice plants strongly influenced fresh body weights of female brown planthopper. The fresh weight of female adult was greatly increased with the increase of nitrogen application to rice plants and the increase was linear (Fig. 3). Females were significantly heavier when reared on plants in N₁₀₀ and N₂₀₀ regimes than in the N₀ regime (Table 2). Phosphorus fertilization to rice plants at the rates of P₂₀ and P₄₀ also increased fresh weight of brown planthopper when compared to no phosphorus fertilizer (P₀) was added (Fig. 3). There was no significant increase in fresh weight of brown planthopper from P₂₀ to P₄₀ treatment levels (Table 3). The N and P interaction was significant for body weight of freshly developed adult BPH (Table 1) and it was maximum when both nitrogen and phosphorus were applied at higher doses (N₂₀₀ and P₄₀) (Fig. 3). However, brown planthopper reared on rice plants with increased potassium subsidies did not show any change in fresh weights of female adults (Table 4). Interaction of N and K, P and K, and all three nutrients (N, P and K) were insignificant for fresh weight of BPH adult (Table 1).

DISCUSSION

The present study showed that the number of BPH and their weight was increased when fed on high nitrogen regimes host plants, while on low nitrogen regimes they were reduced. These results were also in agreement with other studies (Heinrichs and Medrano, 1985; Lu *et al.*, 2004). They reported that the number of BPH and dry mass from one pair of parents were significantly higher in high nitrogen plants. Body weight and number of BPH increased with the increasing level of nitrogen fertilizer on both susceptible and resistant rice varieties (Heinrichs and Medrano, 1985; Prasad *et al.*, 2003, 2005). Application of nitrogen fertilizer produced more tillers and biomass of rice (Salim, 2002a; Chau *et al.*, 2003) which resulted in a thick and humid canopy that might provide a favourable microenvironment for population development of BPH (Lu *et al.*, 2007). Salim (2002a) reported that increase in nitrogen induced succulence in rice plants which makes them more prone to insect pests. Moreover, the high BPH population in nitrogen applied plants might be due to an increase in soluble protein and free sugar content in rice sap. Numbers of studies showed that soluble amino acid in plants increase nutritional value for insects. (Hu *et al.*, 1986; Kajimura *et al.*, 1995).

The number of BPH produced and dry weight gained from one pair of BPH markedly increased by phosphorus fertilization to rice plants (Table 3). Some authors reported that, phosphorus supplementation did result in enhanced population density (Slamn, 2002; Schade *et al.*, 2003; Huberty and Denno, 2006) and increased body size (Janssen, 1994; Busch and Phelan, 1999; Huberty and Denno, 2006) of different insects.

The number of BPH and dry weight were markedly reduced when potassium fertilizer was applied to rice plants at the highest dose (Table 4). This might be due to decrease in soluble protein and free sugar content in those plants. Salim (2002b) reported that deficiency of K in rice plants increased population build up of white backed planthopper, *Sogatella furcifera* and application of high dose of K to rice plants decreased population build up of the insect. Higher rate of potash fertilizer was associated with lower BPH population (Samiayyan and Janarathanan, 1988, 1990). Plants fertilized with potassium either alone or in combinations with others were infested significantly with the lowest population densities of *Imposca* spp. and *Aphis gossypii* and were infested with moderate numbers of *Bemisia tabaci* (El-Zahi *et al.*, 2012). The negative effects of K fertilizer were also shown by Parihar and Upadhyay (2001) on leafhoppers and mites.

CONCLUSION

Application of nitrogen increased population growth of BPH. Phosphorus fertilization showed a little or no effect on BPH growth but fertilization with the highest rate of potassium showed reduction effect. The rice growing areas where BPH populations grow with better ecological fitness due to result of application of high nitrogen fertilizer could be vulnerable to BPH outbreaks.
